## Average-case complexity and statistical inference

We give an example of the sort of question we will look at. The idea is to 'hide' some structure within a high-dimensional random object. We may then ask if we can *detect* this, i.e. whether we can distinguish the vanilla random object from the random object plus planted structure, also if we may recover, i.e. 'find' the planted structure from within the random object.

A favourite combinatorial random object is the Erdős–Rényi random graph,  $G_{n,1/2}$ , take n vertices and between each pair of vertices independently place an edge with probability 1/2. We are interested in the typical behaviour for large n. The structure we plant is a clique, i.e. between a subset  $S^*$  of the vertices of the graph, we place all the possible edges. Now, the random graph  $G_{n,1/2}$  without the planted structure will naturally have some cliques by chance, and indeed the largest of these will have size approximately  $2 \log_2 n$  with probability tending to 1 as  $n \to \infty$ ; which suggests it might not be possible to detect or recover a planted structure of size smaller than  $2 \log_2 n$ . This turns out to be true, as we shall see. Interestingly, there is another phase transition. Fast algorithms finding the clique, e.g. picking the vertices of highest degrees, are only known when the planted clique has size about  $n^{1/2}$  or higher; which is considerably larger than  $2 \log_2 n$ . There is some 'evidence' that this  $n^{1/2}$  threshold is fundamental: by evidence we mean rigorous statements we can prove which suggest that there are no polynomial time algorithms.

These ideas will be made precise in the course as we investigate what forms this evidence can take. We illustrate the techniques on three running examples, planted clique, as described above, as well a generalisation of it planted dense subgraph, and a Gaussian planted structure problem biclustering see Appendix A for a list and the phase transitions in each model. This area is very active and many of the techniques and results presented here have been developed within the last decade and some within the last year.

## 1 Detection

#### 1.1 Definitions

**Problem Setup** We specify a dimension n, and parameters (e.g. k size of planted structure,  $\lambda$  strength of 'signal', p, q probabilities of 'community' edges and 'non-community' edges respectively). For each fixed set of parameters we are interested in the behaviour for large n or as  $n \to \infty$ .

For a detection problem, under  $H_0$  the *null hypothesis*, we sample from the probability space  $\mathcal{Q}_n$  and under  $H_1$  the *alternate hypothesis* we sample from the probability space  $\mathcal{P}_n$ . We write  $\mathbb{P}_0(G=g)$  to denote the probability that a random sample G from probability distribution  $\mathcal{Q}_n$  is the deterministic g (and similarly  $\mathbb{P}_1(G=g)$  to denote the same for  $\mathcal{P}_n$ ). We will try to stick to the convention of denoting random variables, random graphs or random matrices by capital letters and deterministic values, graphs and matrices by lower case letters.

A test is a function  $\phi_n$  on the union of the supports of  $\mathcal{Q}_n$  and  $\mathcal{P}_n$ , with  $\phi_n(g) \in \{0, 1\}^1$ . We need a notion of how 'good' a test is at distinguishing  $\mathcal{Q}_n$  and  $\mathcal{P}_n$  and will use risk. The risk of a test  $\phi$ , denoted  $r(\phi)$  is

$$r(\phi) = \sum_{g: \phi(g)=1} \mathbb{P}_0(\phi(G) = g) + \sum_{g: \phi(g)=0} \mathbb{P}_1(\phi(G) = g) = \mathbb{P}_0(\phi(G) = 1) + \mathbb{P}_1(\phi(G) = 0)$$

<sup>&</sup>lt;sup>1</sup>Suppose for now that  $\phi_n$  is deterministic, later we may have random tests.

Observe that it is easy to design a function which achieves risk 1. We can take  $\phi_{\text{guess null}}(g) = 0$  for all g in the support of  $\mathcal{P}_n$  and  $\mathcal{Q}_n$ , or we could take the random test  $\phi_p(g)$  which takes value 1 with probability p and 0 otherwise. Both of these have risk 1 for each input g.

We say a test  $\phi_n$  achieves strong detection between  $H_0$  and  $H_1$  if  $r(\phi_n) \to 0$  as  $n \to \infty$ . Similarly, we say a test  $\phi_n$  achieves weak detection between  $H_0$  and  $H_1$  if there exists  $\varepsilon > 0$ ,  $n_0$  such that  $r(\phi_n) < 1 - \varepsilon$  for all  $n > n_0$ .

We may now define what we mean by EASY and POSSIBLE detection. Say for  $H_0: \mathcal{Q}_n(\alpha, \beta)$  vs  $H_1: \mathcal{P}_n(\alpha, \beta)$  that strong detection for  $H_0$  vs  $H_1$  is EASY for parameters  $\alpha, \beta$  if there exists a test  $\phi_n$  implementable as a polynomial time algorithm such that  $r(\phi_n) \to 0$  as  $n \to \infty$ . The definition for weak detection being EASY is similar, just replace the condition on  $r(\phi_n)$  as required.

Say for  $H_0: \mathcal{Q}_n(\alpha, \beta)$  vs  $H_1: \mathcal{P}_n(\alpha, \beta)$  that strong detection for  $H_0$  vs  $H_1$  is POSSIBLE for parameters  $\alpha, \beta$  if there exists a test  $\phi_n$  such that  $r(\phi_n) \to 0$  as  $n \to \infty$ . In particular  $\phi_n$  may be a brute-force algorithm. The definition for weak detection being POSSIBLE is similar.

Later we will be able to talk about detection problems being HARD if they are POSSIBLE and we have 'evidence of hardness'. We will usually specify which evidence of hardness.

#### 1.2 The spiked matrix model

We define a probability space  $BC_n$  over  $n \times n$  matrices with real entries. The detection problem will be to distinguish between a matrix sampled from the 'null' where all entries normally distributed with mean zero and variance one, from the 'alternate' with a planted submatrix of expected size k which has entries with mean  $\lambda$  and variance one. See Fig 3.

Given the number of vertices n, total community size k and signal strength  $\lambda > 0$ , define the additive (independent) Gaussian model  $\mathrm{BC}_n = \mathrm{BC}_n(k,\lambda)$  as follows. Under  $\mathrm{BC}_n$ , independently for each  $i \in [n] := \{1,2,\ldots,n\}$ , the community label  $\sigma_i$  is sampled such that  $\sigma_i = 1$  with probability k/n and  $\sigma_i = 0$  with probability 1 - k/n, then set  $X_{ij} = \sigma_i \sigma_j$  For each pair of vertices  $i, j \in [n]$  the matrix entry  $Y_{ij}$  is sampled from

$$Y_{ij}|X_{ij} \sim \begin{cases} \mathcal{N}(\lambda,1), & X_{ij} = 1 \quad \text{(i.e. } \sigma_i = \sigma_j = 1) \\ \mathcal{N}(0,1), & X_{ij} = 0. \end{cases}$$

Note that if  $ij \neq kl$  then  $Y_{ij}|X_{ij}$  is independent from  $Y_{kl}|X_{kl}$ . We define the (fixed number) Gaussian model  $BC_n = BC'_n(k, \lambda)$  as above except that we choose a set S uniformly from all subsets of [n] of size k, and set  $\sigma_i = 1$  if  $i \in S$  and  $\sigma_i = 0$  if  $i \notin S$ . Thus in this model we have exactly k 'community' indices.

#### 1.3 When detection in matrix model is EASY

**Lemma 1.1.** Fix  $\alpha, \beta$  such that  $0 < \alpha, \beta < 1$  and  $\beta > \alpha/2 + 1/2$  (i.e. the green region in Fig ??). Let  $Q_n = Q_n(\alpha, \beta)$  be BC(n, 0, 0) and  $P_n = P_n(\alpha, \beta)$  be  $BC(n, k = n^{\beta}, \lambda = n^{-\alpha})$ . Then the strong detection problem is EASY for  $\alpha, \beta$ .

end L1

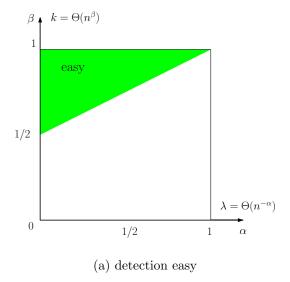

Figure 1: Region considered in Lemma 1.1, see also Figure 3

Proof. (sketch)

We show the follow test distinguishes with high probability. Define  $\phi_{\text{sum}}: \mathbb{R}^{n^2} \to \{0,1\}$  by

$$\phi_{\text{sum}}(x) = \begin{cases} 1, & \text{if } \sum_{i,j} x_{ij} > \frac{1}{2} \lambda k^2, \\ 0, & \text{otherwise.} \end{cases}$$

Recall that if  $X_1 \sim N(\mu_1, s_1^2)$  and  $X_2 \sim N(\mu_2, s_2^2)$  and  $X_1$  and  $X_2$  are independent then the sum is distributed  $X_1 + X_2 \sim N(\mu_1 + \mu_2, s_1^2 + s_2^2)$ . Note under  $H_0$  we have  $n^2$  variables distributed as N(0, 1), and under  $H_0$  we have  $k^2$  variables distributed as  $N(\lambda, 1)$  and  $n^2 - k^2$  distributed as N(0, 1), and thus

$$\sum_{i,j} X_{ij} = \begin{cases} N(0, n^2), & \text{under } H_0, \\ N(\lambda k^2, n^2), & \text{under } H_1. \end{cases}$$

The proof may now be completed using Lemma  $B.2^2$ .

**Lemma 1.2.** Fix  $\alpha, \beta \in (0,1)$  such that either of the following holds  $\beta > \alpha/2 + 1/2$  or  $\beta > 2\alpha$  (i.e. the shaded dashed and non-dashed regions in Fig 2). Let  $Q_n = Q_n(\alpha, \beta)$  be BC'(n, 0, 0) and  $\mathcal{P}_n = \mathcal{P}_n(\alpha, \beta)$  be  $BC'(n, k, \lambda)$ . Then the strong detection problem is POSSIBLE for  $\alpha, \beta$ .

Thuition: we succeed when the difference in means  $\gg$  square-root of the variance. In this case the difference in means of the test statistic is  $\lambda k^2 = n^{-\alpha+2\beta}$ , and the variance is  $n^2$  under both  $H_0$  and  $H_1$ . So this intuition would say we succeed when  $n^{-\alpha+2\beta} \gg n$ , i.e. when  $-\alpha+2\beta>1$ , which is what we are aiming for.

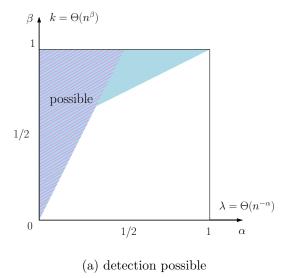

Figure 2: Region considered in Lemma 1.2, since we already have a test for the green region in Figure 1, we need only prove there is a (brute-force) test for the dashed region. See also Figure 3

*Proof.* Note that by Lemma 1.1 we have a test which distinguishes whp for  $\alpha, \beta \in (0,1)$  with  $\beta > \alpha/2 + 1/2$  (i.e. the green region in Fig ??). Thus it suffices to construct a test which distinguishes whp for fixed  $\alpha, \beta \in (0,1)$  with  $\beta > 2\alpha$  (i.e. the purple dashed area in Fig 2.

Let  $\phi_{\text{search}}: \mathbb{R}^{n^2} \to \{0,1\}$  be defined by

$$\phi_{\text{search}}(x) = \begin{cases} 1, & \text{if } \max_{S \subset [n], |S| = k} & \sum_{i,j \in S} x_{ij} > \frac{1}{2} \lambda k^2, \\ 0, & \text{otherwise.} \end{cases}$$

Define the random variable  $T_{\text{search}} = \max_{S \subset [n], |S| = k} \sum_{i,j \in S} X_{ij}$ , i.e. the quantity that is thresholded in  $\phi_{\text{search}}$ .

Under  $H_0$ ,  $T_{\text{search}}$  is the max of  $\binom{n}{k}$  variables,  $T_1, \ldots, T_{\binom{n}{k}}$  where each  $T_i \sim N(0, n^2)$ .

Recall that if  $X_1 \sim N(\mu_1, s_1^2)$  then for constant a, we have  $aX_1 \sim N(a\mu_1, a^2s_1^2)$ . Thus  $n^{-1}T_i \sim N(0, 1)$ , and so we can apply Lemma C.1. (Note the  $T_i$ 's are not independent, they are sums of overlapping parts of the matrix, but we don't need independence to apply the lemma.) By Lemma C.1 whp

$$T_{\text{search}} = \max_{i=1,\dots,m} \frac{1}{n} T_i \leqslant \sqrt{(2+\varepsilon)\log(\binom{n}{k})} \leqslant \sqrt{(2+\varepsilon)k\log n}$$

where we used the fact that  $\binom{n}{k} \leq n^k$ .

Under  $H_1$ , again  $T_{\text{search}}$  is the max of  $\binom{n}{k}$  variables, including the sum over the planted submatrix, and since it is a max it is at least as big as the sum over the planted set  $S^*$ . Let  $T_{\text{planted}} = \sum_{i,j \in S^*} X_{i,j}$ . Since  $T_{\text{planted}}$  is the sum of  $k^2$   $N(\lambda, 1)$  random variables,  $T_{\text{planted}} \sim N(\lambda k^2, k^2)$  and  $\mathbb{E}[T_{\text{planted}}] = \lambda k^2$ .

We want to show  $T_{\rm planted} > \lambda k^2/2$  whp. Since  $T_{\rm planted}$  has expected value  $\lambda k^2$  it is enough to show that whp  $T_{\rm planted}$  is at most  $\lambda k^2/3$  away from its expectation - this shows whp  $T_{\rm planted} > 2\lambda k^2/3$  - see also the chat in Section B. By Lemma B.2, with  $t = \lambda k^2/3$ 

$$\mathbb{P}(|T_{\text{planted}} - \lambda k^2| \ge \lambda k^2/3) \le 2 \exp(-(\lambda k^2/3)^2/(2k^2)) = 2 \exp(-\lambda^2 k^2/6).$$

Now, note that  $2\exp(-\lambda^2 k^2/6) = o(1)$  if  $\lambda k \to \infty$ , i.e.  $n^{\beta-\alpha} \to \infty$  which is true whenever  $\beta > \alpha$ . Hence for  $\beta > \alpha$   $T_{\rm planted} > \lambda k^2/2$  whp. Since  $T_{\rm search} \geqslant T_{\rm planted}$  always. Thus under  $H_1$  whp  $\phi_{search} = 1$  as required.

## 2 Planted Clique

Our approach for the possible and impossible regions of planted clique follows closely that of [1].

### 2.1 When planted clique is POSSIBLE

**Lemma 2.1.** Let  $k = k(n) > 2\log_2 n + 3$ . Then for  $H_0 : G(n, 1/2)$  vs  $H_1 : G'(n, k, 1/2)$  strong detection is POSSIBLE.

For graph g, define  $\omega(g)$  to be the size of the largest clique in g, i.e. the size of the largest set of vertices S such that each pair of vertices in S is connected by an edge in graph g.

*Proof.* Our test will work by thresholding on the size of the largest clique in the graph. Let

$$\phi_n(g) = \begin{cases} 1, & \text{if } \omega(g) > 2\log_2 n + 3, \\ 0, & \text{otherwise.} \end{cases}$$

Then the risk of this test is

$$r(\phi_n) = \mathbb{P}_0(\phi_n = 1) + \mathbb{P}_1(\phi_n = 0) = \mathbb{P}_0(\omega(G) > 2\log_2 n + 3) + \mathbb{P}_1(\omega(G) \leq \log_2 n + 3).$$

Note that the size of the largest clique in the planted model is at least the size of the planted clique (it might be bigger if there is another vertex which happens to be connected to each vertex in the planted clique). Since, in  $P_n$ , we have planted a clique of size  $2 \log_2 n$ , we have

$$\mathbb{P}_1(\phi_n(G) = 0) = \mathbb{P}_1(\omega(G) \leqslant \log_2 n + 3) = 0.$$

Thus the risk simplifies to consider only the size of the largest clique in G(n, 1/2)

$$r(\phi_n) = \mathbb{P}_0(\omega(G) > 2\log_2 n + 3).$$

Let  $N_m$  be the number of cliques of size m. Since  $\mathbb{P}_0(N_m \ge 1) \le \mathbb{E}_0[N_m]$  it suffices to bound the expected number of cliques. (This is an example of the 'first moment method'.)

Then we may calculate

$$\mathbb{E}_0[N_m] = \sum_{S: |S|=m} \mathbb{P}_0(S \text{ is a clique in } G)$$

$$= \binom{n}{m} 2^{-\binom{m}{2}}$$

$$\leq n^m 2^{-m(m-1)/2}$$

$$= (n2^{-(m-1)/2})^m.$$

One may then check that for  $m \le 2\log_2 n + 3$  that  $n2^{-(m-1)/2} \le 1/2$ . And thus for  $m \le 2\log_2 n + 3$ 

$$\mathbb{E}_0[N_m] \leqslant 2^{-m}$$
.

and hence for  $m \leq 2 \log_2 n + 3$ ,  $E_0[N_m] \to 0$  as  $n \to \infty$ .

Hence, since  $\mathbb{P}_0(N_m \ge 1) \le \mathbb{E}_0[N_m]$ , we have  $\mathbb{P}_0(\omega(G) \ge 2\log_2 n + 3) \to 0$  as  $n \to \infty$  and thus we have that the risk of our test goes to zero as n goes to  $\infty$  as required.

end L2

### 3 Likelihood ratio and risk

begin L3

We define the likelihood ratio between discrete probability spaces  $H_0: Q$  and  $H_1: P$  by

$$L(g) = \frac{\mathbb{P}_1(G=g)}{\mathbb{P}_0(G=g)}.$$
(3.1)

Define  $\phi^* = \phi^*(P, Q)$ , the likelihood ratio test to be the following test

$$\phi^*(g) = \begin{cases} 1, & \text{if } L(g) \leq 1, \\ 0, & \text{if } L(g) > 1. \end{cases}$$

**Lemma 3.1.** Suppose P and Q are discrete probability spaces. The test  $\phi^*$  achieves minimal risk over tests to distinguish  $H_0: Q$  and  $H_1: P$ .

*Proof.* (in lectures). 
$$\Box$$

### 3.1 When planted clique is IMPOSSIBLE

For further details see [1](pages 5-9) which we follow in this section.

end L3

# 4 Introduction to the low degree method

begin L4

We say function f strongly<sup>3</sup> separates  $H_0: Q_n$  and  $H_1: P_n$  if for all  $\varepsilon > 0$ ,  $\exists n_0$  such that

$$\max\{\sqrt{\operatorname{Var}_0[f]}, \sqrt{\operatorname{Var}_1[f]}\} \leqslant \varepsilon |\mathbb{E}_1[f] - \mathbb{E}_0[f]|.$$

The next lemma says that strong separation implies that there is a test with risk going to zero.

**Lemma 4.1.** If f strongly separates  $H_0: Q_n$  and  $H_1: P_n$  then there exists a sequence of tests  $\phi_n$  such that the risk of  $r(\phi_n) \to 0$  as  $n \to \infty$ .

*Proof.* Recall Chebyshev's inequality, for X a random variable with  $Var(X) = \sigma^2$  then

$$\mathbb{P}(|X - \mathbb{E}[X]| \geqslant t) \leqslant \frac{\sigma^2}{t^2}.$$

First note we may assume that  $\mathbb{E}_1[f] \geqslant \mathbb{E}_0[f]$  because if not we may work with -f instead.

<sup>&</sup>lt;sup>3</sup>weak separation is defined similarly, by replacing  $\forall \varepsilon$  with  $\exists C$ . One may show that weak separation implies there is a test with risk strictly less than 1.

Let the threshold be the midpoint of the expectations:  $\tau = \frac{1}{2}(\mathbb{E}_1[f] - \mathbb{E}_0[f])$ . And let the test be  $\phi_f(G) = 1$  if  $f(G) \ge \tau$  and  $\phi_f(G) = 0$  otherwise.

Loosely, it is enough for the value f(G) to be close  $\mathbb{E}_0(f)$  to ensure f(G) is small enough that the test classifies G as coming from the null, i.e.  $\phi_f(G) = 0$ . In particular, note that if we have  $|f(G) - \mathbb{E}_0[f]| < \frac{1}{2}(\mathbb{E}_1[f] - \mathbb{E}_0[f])$  then  $f(G) < \tau$  and thus  $\phi_f(G) = 0$ . Hence

$$\mathbb{P}_{0}(\phi_{f}(G) = 1) \leqslant \mathbb{P}_{0}\left(|f(G) - \mathbb{E}_{0}[f]| \geqslant \frac{1}{2}(\mathbb{E}_{1}[f] - \mathbb{E}_{0}[f])\right)$$

$$\leqslant^{\operatorname{Ch}} \frac{\operatorname{Var}_{0}(f(G))}{\frac{1}{4}(\mathbb{E}_{1}[f] - \mathbb{E}_{0}[f])^{2}}$$

$$\leqslant \frac{\varepsilon^{2}}{4} \quad \text{for all } n > n_{0}.$$

This shows that  $\mathbb{P}_0(\phi_f(G) = 0) \to 1$  as  $n \to \infty$ . To show that  $\mathbb{P}_1(\phi_f(G) = 1) \to 1$  as  $n \to \infty$  is similar, one shows that f(G) sufficiently close to  $\mathbb{E}_1[f]$  implies that  $\phi_f(G) = 1$  and one can thus bound the probability that  $\mathbb{P}_1(\phi_f(G) = 0)$ , details left to the reader.

Given a sequence of hypothesis testing problems  $H_0: Q_n$  and  $H_1: P_n$  define the (degree-D) advantage, written  $Adv_{\leq D}$ , by

$$Adv_{\leq D}(P_n, Q_n) = \max_{\deg f \leq D} \frac{\mathbb{E}_1[f]}{\sqrt{\mathbb{E}_0[f]}}.$$
(4.1)

Note we divide by the second moment under the null, rather than the variance under the null. Intuitively (4.1) can be thought of as the fluctuations in the planted model divided by the fluctuations in the null model. The term advantage is because it is meant to give a quantitative value for how much advantage over random guessing one can get by thresholding degree D polynomials.

We may then define notions of EASY and HARD for degree D polynomials. Say

testing problem 
$$H_0: Q_n \text{ vs } H_1: P_n \text{ is } \begin{cases} \text{EASY for degree } D \text{ if } \operatorname{Adv}_{\leq D}(P_n, Q_n) \to \infty \text{ as } n \to \infty \\ \operatorname{HARD for degree } D \text{ if } \operatorname{Adv}_{\leq D}(P_n, Q_n) \to 0 \text{ as } n \to \infty. \end{cases}$$

From this we may finally define low degree polynomial hardness - basically we regard degree  $\log n$  polynomials as 'low degree'. Say a testing problem  $H_0: Q_n$  vs  $H_1: P_n$  is EASY for low degree polynomials if there exists some constant C, such that it is easy for degree  $D = C \log n$ . Likewise we say a testing problem  $H_0: Q_n$  vs  $H_1: P_n$  is HARD for low degree polynomials (or 'low degree hard') if there exists some constant C', such that it is HARD for degree  $D = C' \log n$ .

### 4.1 Linear algebra

Suppose for now that the null  $H_0: Q_n$  is a (sequence of) discrete probability space(s). We define a linear product of functions, with respect to the null:

$$\langle f, g \rangle = \mathbb{E}_0[fg] = \sum_{G} P_0(G) f(G) g(G).$$

Let  $\tilde{Q}_n$  be supported on vectors  $Y = (Y_i)_{i=1}^N$  of length N = N(n) such that each co-ordinate takes values +1 and -1 independently with probability a half. Then for  $\alpha \subseteq [N]$ , i.e.  $\alpha$  is a set of indicies, we may define

$$h_{\alpha} = \prod_{i \in \alpha} Y_i \tag{4.2}$$

**Claim.** The set of functions  $\{h_{\alpha}\}_{{\alpha}\subseteq[N]}$  forms an orthonormal basis for  $\tilde{Q}_n$ . (proof in lectures)

We will need the following lemma.

**Lemma 4.2.** For  $H_0: \tilde{Q}_n$  (as above) and  $H_1: P_n$  a discrete probability space and for  $\{h_\alpha\}_{\alpha\subseteq D}$  (defined (4.2)),

$$\operatorname{Adv}_{\leq D}(P_n, \tilde{Q}_n)^2 = \sum_{|\alpha| \leq D} (\mathbb{E}_1[h_{\alpha}(Y)])^2$$

end L4

## 4.2 When planted clique is HARD

# A List of Planted problems

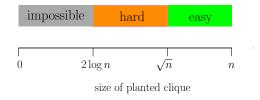

Figure 2: Planted clique.

 $H_0$ :  $G(n, \frac{1}{2})$  random graph on n vertices where each edge is present independently with probability 1/2.  $H_1$ :  $G(n, k, \frac{1}{2})$ , random graph on n vertices where each vertex is part of 'community' S independently with probability k/n. Each edge ij is present independently either with probability 1 if  $i, j \in S$  or with probability

1/2 otherwise.

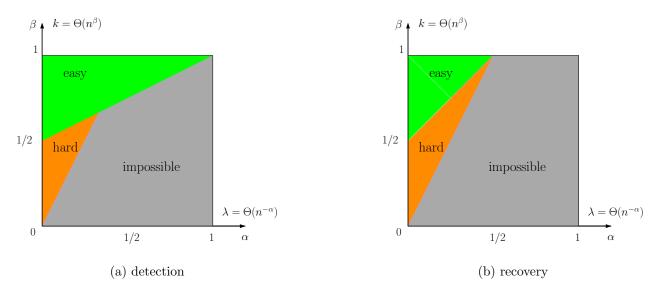

Figure 3: **Spiked Matrix Model** (planted submatrix with elevated mean).  $H_0$ : random  $n \times n$  matrix with each entry independent with distribution N(0,1).  $H_1$ :  $n \times n$  matrix with each index in set S independently with probability k/n. Each entry independent with distribution  $N(\lambda, 1)$  if  $i, j \in S$  and with distribution N(0, 1) otherwise.

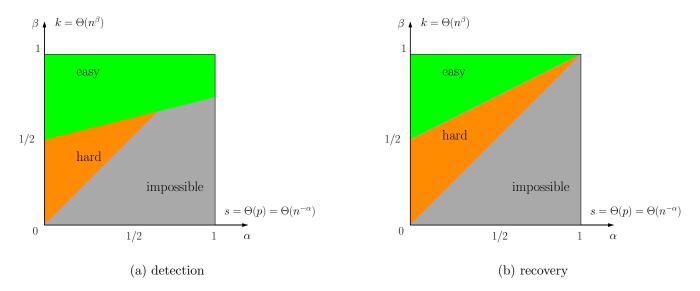

Figure 4: Planted dense subgraph.

 $H_0$ : G(n,q) random graph on n vertices where each edge is present independently with probability q.  $H_1$ : G(n,k,q,s) with s>0, random graph on n vertices where each vertex is part of 'community' S independently with probability k/n. Each edge ij is present independently either with probability q+s if  $i,j \in S$  or with probability q otherwise.

# **B** Concentration Inequalities

Sometimes we are interested in a random variable  $X_n$  which is very likely to fall within some interval  $[a_n, b_n]$  (and this can be very useful for us!). Often we can prove this statement in two steps. First we calculate the expected value. Let  $c_n = \mathbb{E}[X_n]$  and suppose for simplicity that  $c_n = (a_n + b_n)/2$ . The second step is to show it is unlikely that  $X_n$  is far from its expected value  $c_n$ ; i.e. to show  $\mathbb{P}(|X_n - c_n| > (a_n - b_n)/2) \to 0$  as  $n \to \infty$ . Note these two steps together prove that  $X_n$  lies in  $[a_n, b_n]$ 

whp, i.e. that  $\mathbb{P}(a_n \leq X_n \leq b_n) \to 1$  as  $n \to \infty$ .

We say in this case (i.e. when the second step works), that a random variable is *concentrated about its* mean and refer to the bounds below as *concentration inequalities*. We will use these often so collect them in this section of the appendix for easy reference.

**Lemma B.1** (Hoeffding's inequality). Let  $S = X_1 + \ldots + X_n$  where  $X_1, \ldots, X_n$  are independent and  $a \leq X_i \leq b$  for all i. Then

$$\mathbb{P}(\mid S - \mathbb{E}[S] \mid) \geqslant t \leqslant 2 \exp\left(-\frac{2t^2}{n(a-b)^2}\right).$$

**Lemma B.2.** Let  $X \sim N(\mu, \sigma^2)$ . Then

$$\mathbb{P}(|X - \mathbb{E}[X]|) \geqslant t \leqslant 2 \exp\left(-\frac{t^2}{2\sigma^2}\right).$$

# C Probability Background

We will use many properties of the distributions, we collate these here for reference while reading the proofs or doing exercises.

### C.1 General Probability

We say a sequence of events  $E_n$  holds whp 'with high probability' if  $\mathbb{P}(E_n) \to 1$  as  $n \to \infty$ .

### C.2 Normal Distribution

The following lemma shows the max of m N(0,1) variables is not too big. Note the variables  $X_1, \ldots, X_m$  need not be independent.

**Lemma C.1.** Let  $\varepsilon > 0$ . Suppose  $X_1, \ldots, X_m \sim N(0, 1)$ . Then

$$X_{\max} = \max_{i \in 1, \dots, m} X_i \leqslant \sqrt{(2+\varepsilon)\log m}$$

with probability tending to 1 as  $m \to \infty$ .

# D Helpful Combinatorial notation and inequalities

The notation  $\binom{n}{k}$  read 'n choose k' is the number of ways to pick a set of k items from a set of n items,

$$\binom{n}{k} = \frac{n(n-1)\dots(n-k+1)}{k(k-1)\dots 1} = \frac{n!}{(n-k)!k!}$$

and

$$\frac{(n-k+1)^k}{k^k} \leqslant \binom{n}{k} \leqslant n^k.$$

#### D.1 Big 'o' notation

We will use notation O(.), o(.),  $\omega(.)$  and  $\Omega(.)$ .

# Index

O(.), 10 o(.), 10	advantage, 7 hard, 8
$\Omega(.), 10$ $\omega(.), 10$ $r(\phi), 1$ advantage, 7	planted clique, 5 hard, 8 impossible, 6 possible, 5
detection easy, 2	risk, 1
